## II. SUMMARY

Accurate information concerning the statistical distribution of enroute ambient temperatures at airplane cruise altitudes is required for many trade studies and performance calculations, and is particularly important when system performance is highly temperature dependent as, for example, in airplane air-conditioning system studies. This document describes a method of calculating the statistical monthly (January, April, July and October) and annual temperature distribution on any Great Circle route for pressures of 300, 200, 150, 100 and 50 millibars, corresponding approximately to altitudes of 30,000 feet, 40,000 feet, 45,000 feet, 53,000 feet and 68,000 feet.

The route temperature distributions are generated by a computer program. Inputs to the program are the coordinates of the terminal points. Output is in several forms, namely:

1. The route temperature distribution, showing the probability of exceeding any temperature, given in graphical form with the option of tabular form as well.
2. The percentage of the total time that the temperature lies within discrete intervals of specified median and width, given in graphical form with the option of tabular form as well.
3. The mean and standard deviation of the normal curve which best approximates the actual temperature distribution, and the error associated with the normal curve approximation.

The graphical output is illustrated in Figures 6 and 7 for the Johannesburg to London route at 30,000 feet.

Meteorological data based on records compiled over long periods for a selected global network of points furnish the basis for the program.

Sections of an existing program (Boeing Document D6-6833TH, Program No. TAP003) are employed, as a subroutine, for the determination of mean temperatures and standard deviations at equidistant points 100-200'

AD 1546 D

nautical miles apart along a Great Circle route. The results were then used in the earlier program to generate the route mean temperature and the mean value of the enroute standard deviations for many routes, as described in documents D6-15650-2 and D6-15650-4. Presentation of results in this form has the disadvantage that the averaging process obscures the effect of temperature variations along a route. Furthermore, representation of the temperature distribution by a normal curve results in a loss in accuracy. For some cases, and particularly for short East-West routes and for all routes at 40,000 feet, enroute temperature variations are small and the route-mean results will closely approximate the results developed in this document. However in many cases enroute temperature variations are significant, and misleading information about temperature extremes will be obtained if the route-mean results are employed to describe the enroute temperature distribution.

Temperature distributions for specific routes may prove unnecessary voluminous to a user who only requires information for a specific region of the earth. Therefore results are presented for four geographical regions of interest, namely:

1. The continental United States.
2. The continental United States combined with the North Atlantic and Central and Southern Europe.
3. The polar region of the Northern Hemisphere.
4. The equatorial region.

Temperature distributions for these regions are compared with the U. S. Standard Atmospheres, and it is shown that the Hot and Cold Atmospheres are encountered only over limited and often remotely located areas.

The advice and cooperation of Mr. Neal M. Barr (Atmospheric Engineering Group, Aerodynamic Staff) is acknowledged.

### III. INTRODUCTION

The ambient air temperature influences the performance of many airplane systems. Accurate information about this temperature is, therefore, of prime importance not only for trade studies but also for performance calculations.

Many different methods of estimating representative ambient temperature distributions have been used. One approach is to consider just the defined values of Standard, Hot and Cold Atmospheres, and to assume that these occur in fixed proportions (90 percent, 10 percent, 0 percent, for example). Such an approach is clearly very arbitrary and is unlikely to yield accurate results. Some of the shortcomings of this method are avoided by using the route-mean temperature data which have been compiled for many Great Circle routes (Reference 1). Route data in Reference 1 are given in the form of the route mean temperature, the mean value of the enroute standard deviations, and the temperatures that are not exceeded 50 percent, 75 percent and 85 percent of the time. The effect of inflight temperature variations is not reflected in these data and therefore information about temperature extremes calculated from the given mean temperature and standard deviation values, may be misleading.

The method of calculation described in this document avoids the approximations introduced in employing the route-mean data of Reference 1 to determine the enroute temperature distribution of a studied route, and the error involved in approximating the actual distribution by a normal curve. Both the developed method and the route-mean method use the same meteorological data. The deviation in the information about temperature extremes between the two methods is dependent on the magnitude of the enroute temperature variation, and this is in turn a complex function of the route, the altitude and the time of the year. In general, the difference increases with length of route, is greater for North-South than East-West routes, and is comparatively high at an altitude of 53,000 feet and low at 40,000 feet.

#### IV. CALCULATION OF TEMPERATURE DISTRIBUTION ON A GREAT CIRCLE ROUTE

##### A. METEOROLOGICAL DATA

Meteorological data, based on records compiled over long periods, have been obtained for a network of 1117 points covering the surface of the earth. The points are located at every latitude which is an exact multiple of five degrees. Within  $60^\circ$  latitude of the equator, the points are located at every longitude which is an exact multiple of ten degrees; on those latitudes which are farther than  $60^\circ$  from the equator the points are located at every longitude which is an exact multiple of twenty degrees. Each pole is represented by one point. The mean and standard deviation of a normal distribution fitted to the actual temperatures over a period of a month are recorded for each point. Data are available for January, April, July and October, these months being assumed to be representative of the seasons; and for pressures of 300, 200, 150, 100 and 50 millibar corresponding approximately to altitudes of 30,000 feet, 40,000 feet, 45,000 feet, 53,000 feet and 68,000 feet. Thus a total of 44,680 data values are available.

##### B. GREAT CIRCLE ROUTE CALCULATION

If the geographical coordinates of the terminals of a route are specified, the Great Circle route may be determined by standard methods (Reference 2 for example). The coordinates of most major airports can be found in Reference 1.

##### C. CALCULATION OF ROUTE TEMPERATURE DISTRIBUTION

If a route is divided into a number of equidistant points, the mean temperature ( $m_i$ ), and standard deviation ( $\sigma_i$ ) at each point (for a given month and altitude) may be obtained by interpolation from adjacent data points (Reference 2). Then if the temperature at any

AD 1546 D

point (1) is distributed normally, the probability that the temperature  $T$  at this point is less than or equal to any specified temperature  $\vartheta$  is, by definition:

$$P(T \leq \vartheta) = F_N(\vartheta)_i = \frac{1}{\sqrt{2\pi}\sigma_i} \int_{-\infty}^{\vartheta} e^{-\left(\frac{T-m_i}{2\sigma_i^2}\right)^2} dT \quad (1)$$

The probability that the temperature  $\vartheta$  is exceeded is given by

$$P(T > \vartheta) = 1 - F_N(\vartheta)_i \quad (2)$$

If the distance between points is chosen so that the temperature and standard deviation can be assumed constant during each flight increment, then the probability for the whole route of any specified temperature  $\vartheta$  being exceeded is given by

$$P_R(T > \vartheta) = 1 - F_R(\vartheta) = \frac{\sum_{i=1}^n (1 - F_N(\vartheta)_i)}{n} \quad (3)$$

An example of this method, using hand calculations to determine the cumulative probabilities, is shown in figures 1 and 2. In order to limit the number of calculations, the example uses larger temperature steps and fewer significant figures. The difference between the temperature distribution at selected points and the route temperature distribution is illustrated in figure 2.

The probability of the temperature falling within a specified interval is given by:

$$P(\vartheta < T \leq \vartheta + \Delta\vartheta) = F_R(\vartheta + \Delta\vartheta) - F_R(\vartheta) \quad (4)$$

Assuming that the months of January, April, July and October are representative of the four seasons, the annual probabilities may be obtained. Thus:

$$P_{RA}(T > \mathcal{V}) = 1 - F_{RA}(\mathcal{V}) = \frac{\sum_{i=1}^4 (1 - F_R(\mathcal{V}))}{4} \quad (5)$$

$$P_{RA}(\mathcal{V} < T \leq \mathcal{V} + \Delta \mathcal{V}) = F_{RA}(\mathcal{V} + \Delta \mathcal{V}) - F_{RA}(\mathcal{V}) \quad (6)$$

#### D. FITTING OF A NORMAL CURVE

For most routes the temperature distribution closely approximates a normal curve. Since normal curves may be defined by specifying just the mean temperature and standard deviation, it is worthwhile determining the normal curve most closely approximating the actual distribution.

The mean temperature of the normal curve is calculated from the actual temperature which is exceeded 50% of the time and from temperatures having the defined probabilities of  $\pm \sigma/2$  and  $\pm \sigma$ , thus averaging out discrepancies in any single value and giving:

$$m_F = \frac{1}{5} (\mathcal{V}_{-\sigma} + \mathcal{V}_{-\sigma/2} + \mathcal{V}_{50} + \mathcal{V}_{\sigma/2} + \mathcal{V}_{\sigma}) \quad (7)$$

The standard deviation is found by a similar method, averaging values at  $\pm \sigma/2, \pm \sigma, \dots, \pm 3\sigma$ , and giving:

$$\sigma_F = \frac{1}{12} \left[ \sum_{i=1}^{2N-1} ((\mathcal{V}_i - m_F)/\gamma) + \sum_{i=1}^{2N-1} ((\mathcal{V}_i - m_F)/\gamma) \right] \quad (8)$$

The mean and maximum deviations in  $(1 - F_R(\mathcal{V}))$  between the actual distribution and the fitted curve are calculated in order to indicate the accuracy of the curve-fitting.

#### E. CALCULATION OF A PROBABLE REGIONAL TEMPERATURE DISTRIBUTION

The available meteorological data can also be utilized to generate a probable temperature distribution that would apply to a geographical region of the earth rather than individual routes. The less voluminous results applicable to an airplane typically operating over the specified region are obtained at the expense of averaging

AD 1546 D

the temperature profiles over the region.

A method of calculation similar to Paragraph IV, C is used to generate the regional temperature distribution based on the meteorological data points located within the specified region. The spheroid shape of the earth is accounted for by giving area-balanced weights to individual points. Results are given in Appendix A.

## V. DESCRIPTION OF PROGRAM

A complete listing of the computer program for calculating enroute temperature distributions is given in Appendix B. It can be seen from the listing that the program is divided into a main program, five subroutines and a function subprogram. The main program handles input and output routines, and directs control to the subroutines and the function subprogram. The meteorological data is stored on a tape-unit (called TAPE for cross-reference) assigned to the author. The subprograms have the following functions:

1. Subroutine TEMP.

Sections of an existing program (ref. 2) are used for generating mean temperatures and standard deviations at equidistant points 100-200 nautical miles apart along the specified route.

2. Subroutine DISTR.

~~Determines~~ the statistical temperature distribution for the whole route from the mean and standard deviation data for the individual points.

3. Subroutine FITNC.

~~Determines~~ the mean and standard deviation of the normal curve most closely approximating the calculated distribution curve.

4. Subroutine PINT.

Determines the probability of the temperature being within intervals of given median and width. The system of median temperatures are centered around the Standard Atmosphere temperature.

5. Subroutine WBIN

Prepared calculated data for input to the CDC-6600 system tape-writing subroutine WRTETP (ref. 4).

6. Function subprogram CNORML

This subprogram calculates the cumulative probability for a normal distribution, given the mean and standard deviation and the region for which the probability is required (ref. document PS-497, Program Library Department).

AD 1546 D

REV SYM

**BOEING**

NO. D6-58402

PAGE

13

6-7000

Input for the program is described in Appendix C, and sample data for the route Johannesburg to London are included for illustration. It should be noted that exactly antipodal points must not be specified as terminals of a route since such points do not give a uniquely defined Great Circle route. Furthermore, meteorological data are not available on the 50 millibar (68,000' altitude) level south of latitude 55 S. A diagnostic is printed if the Great Circle route enters this region.

In order to reduce core storage requirements the DIMENSION statements have been written so that not more than two altitudes can be handled in any one run, and routes are restricted to a maximum length of 11,000 nautical miles.

Output data are in the form of graphs and tables and are self-explanatory. The plots are not labeled by route, but may be identified by the fact that they are generated in the same order that the routes are inputted. Tabular and graphical output corresponding to the input of Appendix C are shown in figures 5 through 7.

Appendix D shows a complete deck assembly and lists the required control cards. The Fortran nomenclature is shown in Appendix E. The core storage requirement is 110000<sub>8</sub> and the central processor time is approximately equal to

$$CPT = 21.5 + 3.8 \times NALT \times NROUTE \text{ seconds}$$

## VI. EXAMPLE

### A. ROUTE TEMPERATURE DISTRIBUTION

Use of the program may be illustrated by considering a specific route, and Johannesburg to London at 30,000' has been selected. As this is a long route (4896 N.M.) and in a South-North direction, considerable enroute temperature variations can be expected. This is confirmed by reference to figure 3, which shows isotherms at 30,000' in January. Figure 4 shows that the standard deviations varies noticeably too.

The mean temperature and standard deviation for 26 equispaced points along the route are shown in figure 5, which also shows temperatures having a 50, 75 and 85% probability of not being exceeded. These values could also be obtained from the graphical plot of figure 6, and can be compared with values obtained using the route-mean method of reference 1. For the month of January, the comparison shows:

<u>Probability of Not Exceeding</u>	<u>Enroute Temperature Method</u>	<u>Route-Mean Method</u>
50%	-32.3F	-38 C $\approx$ -36F
75%	-24.9F	-37 C $\approx$ -35F
85%	-22.6F	-36 C $\approx$ -33F

Figure 5 shows the mean and standard deviation of the normal distribution curve most closely resembling the actual temperature distribution, and also the error associated with the normal curve approximation. It can be seen that in this case, the normal curve is not a particularly good approximation. A comparison for the month of January with the values listed in reference 1 gives:

	<u>Enroute Temperature Method</u>	<u>Route-Mean Method</u>
Mean Temperature	-36.1F	-38 C $\approx$ -36F
Standard Deviation	-13.4F	2 C $\approx$ 4F

AD 1546 D

It can be seen that the route-mean method gives misleading information about the extremes of temperature that will be encountered on this route and this method, originally not intended to describe the enroute temperature distribution but frequently used in this capacity, should not be used where considerable enroute temperature variations can be expected.

It is interesting to apply the different methods of determining route temperatures to the calculation of the operating penalty of a system. Consider, as an example, the ram drag of the model 747 air conditioning system at .85 MN cruise. The ram drag is plotted in Figure 8 as a function of ambient temperature, with temperature histograms based on the statistical and route-mean methods superposed. The average route ram drag may be compared, giving:

<u>Method</u>	<u>Average Drag lb/Airplane</u>
Enroute temperature	799
Route-Mean	396
Standard Day 90% } Hot Day 10% }	415

It can be seen that in this case the route-mean and Standard/Hot day methods seriously underestimate the average drag, and hence the average airplane penalty.

#### B. REGIONAL TEMPERATURE DISTRIBUTION

Appendix A introduces the use of the available meteorological data to generate a probable temperature distribution applicable to a specified region of the earth, thereby eliminating the high degree of idealization inherent to the use of standardized atmospheres. To illustrate the use of the generated data, an example involving the identical airplane-system as in the previous example will be presented. Two of the selected geographical regions in Appendix A (Continental United States and Equatorial region) at the 30,000 foot altitude will be studied.

From the annual temperature distribution curves for the two regions at the given altitude (Figures 14 and 17) one can easily obtain the

AD 1346 D

probabilities on 5 degrees Fahrenheit intervals for calculation of the average ram drag, as was done for an individual route in the previous section. Figure 10 gives the probability histograms for the two regions superposed on the ram drag curve. Comparison of the average ram drag gives:

	Average drag lb/airplane
Standard Day 90% } Hot Day 10% }	415
Probable temp. distribution over the Continental United States	447
Probable temp. distribution over the Equatorial region	1260

It is seen that for the given example, the adopted combinations of the standardized atmospheres yields an acceptable value of the average drag if applied over the Continental United States. If another airplane system, having a different temperature dependence, was being studied, this might not have been the case. Taken over the equatorial region it is found that 90% Standard Day, 10% Hot Day seriously under-estimates the average drag, in spite of the fact that Hot Day (Hot Day = Std. Day + 40F at 30,000 ft.) is found to be exceeded < 1% of the year when focusing the entire equatorial region of the earth. Likewise it can be seen that temperatures as low as Standard Day are extremely unlikely to be encountered over this area, making an assumption of 90% of the time at Standard Day unrealistic. Finally if the interest is founded on localized areas where the concept of Hot Day applies (areas recording temperatures exceeding Hot Day 10% of the time), one will find that such an area at 30,000 feet exists over South East Asia. Calculations of the average drag based on the probable temperature distribution over this area will result in a value exceeding the one obtained for the Equatorial region, showing that if 10% Hot Day is a realistic figure, one can not designate Standard Day condition to the remaining portion of the time.

## VII. CONCLUSIONS AND RECOMMENDATIONS

The method for determining enroute temperatures developed in this document generates results which are limited in accuracy only by the accuracy of the meteorological data on which they are based. The computer program is simple to use and presents results in convenient tabular and graphical forms. Therefore, it is recommended that the statistical method should always be used for generating enroute temperature distributions. For some routes, and particularly for short East-West routes, the route-mean method (Reference 1) gives acceptable approximations of the enroute temperature distribution.

Use of the regional temperature data to designate a probable temperature distribution eliminates the high degree of idealization inherent to the use of standardized atmospheres, thereby greatly improving the accuracy and reliability of employed data. It is recommended that the regional temperature data be used instead of standardized atmospheres in determining typical operating temperatures for airplanes and airplane systems.

APPENDIX A  
USE OF THE AVAILABLE METEOROLOGICAL DATA  
TO GENERATE REGIONAL TEMPERATURE DISTRIBUTIONS

The concepts of Standard, Hot and Cold Atmosphere (References 5 through 7) are commonly combined to designate a probable temperature distribution for trade studies or performance calculations on the typical operation condition of an airplane system being studied. Any such combination of the standardized atmospheres (i.e., 90 percent of the time at Standard Day and remaining 10 percent at Hot Day) is likely to involve a substantial degree of idealization of any probable temperature distribution and the risk for misinterpretations becomes apparent. If Standard Day condition is encountered during the major part of the time, as in above example, the probability of experiencing Hot Day is extremely remote. On the other hand, if the interest is focused on the localized areas where Hot Day temperature actually is being exceeded the specified percentage of the time, it is improbable that temperatures as low as Standard Day will be encountered.

Using the available meteorological data, it is possible to generate a more realistic temperature distribution curve applicable to a specified region of the earth, thereby eliminating the uncertainties inherent in the use of the standardized atmospheres. The developed data becomes applicable to an airplane in traffic of about equal density over the specified region. Data for four regions of common interest has been generated. These are:

1. Continental United States with adjacent border areas (52.5N to 22.5N latitude and 65W to 125 W longitude).
2. Area 1 combined with North Atlantic, Central and Southern Europe (Area 1 plus 62.5N to 37.5N latitude and 25E to 65W longitude).
3. Polar region of Northern Hemisphere (90N to 62.5N latitude).
4. Equatorial region (22.5N to 22.5S latitude).

Data pertinent to any other region of the earth of interest can, upon request, be generated.

PAGE 30

6-7000

Figures 10 through 13 give the temperatures that are probable to be exceeded 99, 90, 50, 10 and 1 percent of the year over the different specified regions. The three standardized atmospheres (Standard, Hot and Cold) are superposed for comparison and reference. The temperatures at the different levels where calculations have been carried out (10,000, 18,000, 30,000, 40,000, 45,000, 53,000 and 68,000 feet) are interconnected in the most probable way.

Figures 14 through 17 give the complete seasonal and annual (arithmetic mean of the four seasons) temperature distribution at 30,000 ft. altitude. Similar curves can be made available for any region and altitude. Figure 18 is a summary table of data from Figures 10 through 13, everything being referred to Standard Day condition at each altitude.

### INPUT DATA DESCRIPTION AND ARRANGEMENT

The table below describes the preparation of the data input cards.

CARD	LOCATION COLUMN	INPUT ITEM	MODE OF NUMBER	DESCRIPTION
1	1-6	NALT	INT.	Number of altitudes to be used throughout the calculations.
	7-12	ALTI(1)	INT.	First altitude (feet) for which data is to be calculated.
	13-18	ALTI(2)	INT.	Second altitude in calculation. ALTI(2) must be larger than ALTI(1) (altitudes entered in order of increasing numbers). ALTI(2) omitted if NALT equal to one.
2	1-6	OPT(1)	INT.	Option; = 1 if printing of all calculated data, = 0 if not
	7-12	OPT(2)	INT.	Option; = 1 if temp. output in Fahrenheit, = 2 if Celsius
	13-18	OPT(3)	INT.	Option; = 1 if probability on intervals desired, = 0 if not
	19-30	TINT	REAL	Width of temp. intervals, can be omitted if OPT(3) = 0, OPT(2) controls input unit.
3	1-6	NROUTE	INT.	Number of routes to be calculated in the specified manner.
4	1-80	COMMENT	ALPHANUM	Description of route; This card must not be omitted.
5	1-12	GLAT(1)	REAL	Start point latitude in degrees and minutes to the conventional notation; north latitudes positive, south negative.
	13-24	GLNG(1)	REAL	Start points longitude in degrees and numbers to the conventional notation; west longitudes positive, east negative.
	25-36	GLAT(2)	REAL	End point latitude
	37-48	GLNG(2)	REAL	End point longitude

AD 1546 D

Input data to process first work is now complete. For additional routes, repeat cards 4 and 5 until specified NROUTE are imputed.

Input data to generate the sample case output shown in figures 5 through 7 are listed below:

### FORTRAN NOMENCLATURE

The following table gives the nomenclature for the main program and the subprograms. Only the more significant terms are included. The nomenclature for terms, whose values are stored in the COMMON region of the computer, are given first. In the table, dummy subscripts I, J and K are used to denote 1, 2 and 3rd dimension respectively.

#### NOMENCLATURE FOR THE COMMON STORAGE

FORTRAN SYMBOL	DESCRIPTION	UNITS
A (I,J,K)	Meteorological data. Coded in the form <del>faa</del> abb, where <del>faa</del> is mean-temp. in <del>tenths</del> and bb is standard deviation in <del>tenths</del> also. I denotes location on the earth J denotes month K denotes altitude	C (Celius)
DEER(I)	Temperatures calculated and used for one altitude	C
DIST(I)	Cumulative distance from start terminal to point i	N.M.
EAVR(I)	Average error in fitted normal curve	---
EMAX(I)	Maximum error in fitted normal curve	---
ITHI	Upper boundary of temp. range considered for one altitude.	C
ITLO	Lower boundary of temp. range considered for one altitude.	C
ITR	Number of temperature steps used in calculation	---
I55S	Indicator for region of earth where meteorological raw data are not available (68000 ft, south of 55 S.lat.)	---
LALT(I)	Altitude	FEET

AD 1346 D

FORTRAN SYMBOL	DESCRIPTION	UNITS
LM3	Number of points i on the route	---
MTH	Months number. 1 through 5 per following denotation. 1 for January 2 for April 3 for July 4 for October 5 for Annual	---
NINT	Number of intervals employed for probability on intervals	---
PINV(I,J)	Probability on individual temp. intervals of given width and <b>median</b> temperature.	N (Normalized)
PRI(I,J)	Cumulative probability value at lower boundary of interval	N
PROB(I,J)	Cumulative probability to exceed temp. values given by DEGR(I)	N
SCALC(I)	Standard deviation for fitted normal distribution curve	C
STDN(I,J,K)	Standard deviation for the points along the route.	C
TIM(I)	Interval <b>median</b> temperature	C
TMN(I)	Mean values for fitted normal distribution curves	C
TNMP(I,J,K)	Mean temp. for the points along the route	C
TPR(I,J)	Temperatures corresponding to .50, .75 and .85 probability <u>not</u> to exceed	C
USSA(I)	United States Standard Atmosphere, 1962	C

#### ADDITIONAL NOMENCLATURE FOR THE MAIN PROGRAM AND SUBPROGRAMS

For complete nomenclature to subroutine TEMP, see Document D6-6833TN.

ALTI (I)	Altitudes on which calculations are to be carried out.	Feet

# LIST OF NOMENCLATURE

<u>Symbol</u>	<u>Description</u>
$F_N (T)_i$	Cumulative probability that T shall be less than or equal to $T$ , for point "i" of a route.
$F_R (T)$	Cumulative probability ( $T \leq T$ ) for the entire route.
$F_{RA} (T)$	$F_R (T)$ for the annual case
$m_F$	Mean value for fitted normal curve.
$m_i$	Mean value for point "i" of a route.
$n$	Number of points on a route, terminals included.
$\sigma_F$	Standard deviation for fitted normal curve.
$\sigma_i$	Standard deviation for point "i" of a route.
$T_{50}$	Temperature for $F_R$ equal to 50 percent.
$T_y$	Interpolated temperature used when fitting a normal curve.
$T$	Function that describes the occurrence of different temperatures $T$ at a given point. In this case a Gaussian function.
$T$	Independent variable (temperature)

## II. SUMMARY

Accurate information concerning the statistical distribution of enroute ambient temperatures at airplane cruise altitudes is required for many trade studies and performance calculations, and is particularly important when system performance is highly temperature dependent as, for example, in airplane air-conditioning system studies. This document describes a method of calculating the statistical monthly (January, April, July and October) and annual temperature distribution on any Great Circle route for pressures of 700, 500, 300, 200, 150, 100 and 50 millibars, corresponding approximately to altitudes of 10,000 feet, 18,000 feet, 30,000 feet, 40,000 feet, 45,000 feet, 53,000 feet and 68,000 feet.

The route temperature distributions are generated by a computer program. Inputs to the program are the coordinates of the terminal points. Output is in several forms, namely:

1. The route temperature distribution, showing the probability of exceeding any temperature, given in graphical form with the option of tabular form as well.
2. The percentage of the total time that the temperature lies within discrete intervals of specified median and width, given in graphical form with the option of tabular form as well.
3. The mean and standard deviation of the normal curve which best approximates the actual temperature distribution, and the error associated with the normal curve approximation.

The graphical output is illustrated in Figures 6 and 7 for the Johannesburg to London route at 30,000 feet.

Meteorological data based on records compiled over long periods for a selected global network of points furnish the basis for the program.

Sections of an existing program (Boeing Document D6-6833TN, Program No. TAP003) are employed, as a subroutine, for the determination of mean temperatures and standard deviations at equidistant points 100-200

#### IV. CALCULATION OF TEMPERATURE DISTRIBUTION ON A GREAT CIRCLE ROUTE

##### A. METEOROLOGICAL DATA

Meteorological data, based on records compiled over long periods, have been obtained for a network of 1117 points covering the surface of the earth. The points are located at every latitude which is an exact multiple of five degrees. Within  $60^\circ$  latitude of the equator, the points are located at every longitude which is an exact multiple of ten degrees; on those latitudes which are farther than  $60^\circ$  from the equator the points are located at every longitude which is an exact multiple of twenty degrees. Each pole is represented by one point. The mean and standard deviation of a normal distribution fitted to the actual temperatures over a period of a month are recorded for each point. Data are available for January, April, July and October, these months being assumed to be representative of the seasons; and for pressures of 700, 500, 300, 200, 150, 100 and 50 millibar corresponding approximately to altitudes of 10,000 feet, 18,000 feet, 30,000 feet, 40,000 feet, 45,000 feet, 53,000 feet and 68,000 feet. Thus a total of 62,550 data values are available.

##### B. GREAT CIRCLE ROUTE CALCULATION

If the geographical coordinates of the terminals of a route are specified, the Great Circle route may be determined by standard methods (Reference 2 for example). The coordinates of most major airports can be found in Reference 1.

##### C. CALCULATION OF ROUTE TEMPERATURE DISTRIBUTION

If a route is divided into a number of equidistant points, the mean temperature ( $m_i$ ), and standard deviation ( $\sigma_i$ ) at each point (for a given month and altitude) may be obtained by interpolation from adjacent data points (Reference 2). Then if the temperature at any

AD 1546 D

REV SYM

A

**BOEING**

NO. D6-58402

PAGE 9

6-7000

Input for the program is described in Appendix C, and sample data for the route Johannesburg to London are included for illustration. It should be noted that exactly antipodal points must not be specified as terminals of a route since such points do not give a uniquely defined Great Circle route. Furthermore, meteorological data are not available on the 700, 500 or the 50 millibar (10,000', 18,000' or 38,000' altitude) levels south of latitude 55 S. A diagnostic is printed if the Great Circle route enters this region on those altitudes.

In order to reduce core storage requirements the DIMENSION statements have been written so that not more than two altitudes can be handled in any one run, and routes are restricted to a maximum length of 11,000 nautical miles.

Output data are in the form of graphs and tables and are self-explanatory. The plots are not labeled by route, but may be identified by the fact that they are generated in the same order that the routes are input. Tabular and graphical output corresponding to the input of Appendix C are shown in Figures 5 through 7.

Appendix D shows a complete deck assembly and lists the required control cards. The Fortran nomenclature is shown in Appendix E. The core storage requirement is 110000g and the central processor time is approximately equal to

$$CPT = 21.5 + 3.8 \times NALT \times NROUTE \text{ seconds}$$
